Layered material heterostructures (LMHs) can be used to fabricate electroluminescent devices operating in the visible spectral region. A major advantage of LMH-light emitting diodes (LEDs) is that electroluminescence (EL) emission can be tuned across that of different exciton complexes (e.g. biexcitons, trions, quanta-tions) by controlling the charge density. However, these devices have an EL quantum efficiency as low as ∼10⁻⁴. Here, we show that the superacid bis-(trfluoromethane)sulfonimide (TFSI) treatment of monolayer WS₂-LEDs boosts EL quantum efficiency by over one order of magnitude at room temperature. Non-treated devices emit light mainly from negatively charged excitons, while the emission in treated ones predominantly involves radiative recombination of neutral excitons. This paves the way to tunable and efficient LMH-LEDs.

Transition metal dichalcogenide monolayers (1L-TMDs) are ideal to study light-matter interactions and many-body effects at the atomic scale[1–3]. Compared to bulk semiconductors[2], the reduced dielectric screening combined with the spatial confinement of charge carriers[1] favours the formation of various excitonic complexes which can be controlled by modulation of the carrier density[1–8]. Thus, 1L-TMDs photoluminescence (PL) spectra host features arising from formation of charged[4–8] and neutral[9–12] exciton complexes.

Layered material heterostructures (LMHs) combining single layer graphene (SLG), 1L-TMDs, and hexagonal boron nitride (hBN), from 1L-hBN to hundreds of layers, are promising for electronics[13, 14], photonics[15], and optoelectronics[16, 17]. Direct bandgap 1L-TMDs and LMHs can be made to emit light-emitting diodes (LEDs)[18–27], with fast modulation speed (up to GHz)[7, 25, 28], and emission wavelength tunability[6, 7, 25] besides multi-spectral (visible~618nm[21–23] to near-infrared~1160nm[29, 30]) emission.

In 1L-TMD-based LEDs, the electroluminescence (EL) efficiency (ηEL), i.e. ratio between emitted photons and injected electrons (e)[19, 20], depends on the optical emission of the material[30, 37], as well as on its doping level[6, 38–41]. In doped 1L-TMDs, the PL and EL emission originates from either negative (X⁻)[28, 33, 34, 38] or positive (X⁰)[6, 19, 20] trions, depending on the type of doping. However, 1L-TMD-LEDs based on trionic emission show low ηEL (typically<0.05%[19, 20]) with respect to neutral exciton (X⁰) emission (typically ηEL<1%[6, 7, 31, 32, 38, 39]). This difference in ηEL occurs due the small (∼30meV) binding energy of trions[42]. Since the X⁻ binding energy is close to the lattice thermal energy at room-temperature (RT~300K,~25.2meV), trions dissociate[2]. An excess of free-carriers decreases the available phase-space filling for exciton complexes, due to Pauli blocking, with a reduction of trion and exciton binding energies[43] and oscillator strengths[44] (i.e. the probability of absorption/emission of electromagnetic radiation[45]).

In 1L-TMDs, low light-emission efficiency is observed in both EL (ηEL ∼10⁻⁴[33, 34] to~1%[6, 7, 31, 32, 38, 39]) and PL (ηPL ∼10⁻³[36, 40] to~5%[1–3]). ηPL is defined as the ratio between emitted and absorbed photons[19, 20]. Thus, several chemical approaches were suggested[46] to enhance ηPL, such as treatment with sodium sulphide[47], 2,3,5,6 tetrafluoronitro tetracyanoquinodimethane (F4TCNQ)[11, 48], tris(4-bromophenyl)ammoniumyl hexachloroantimonate (magic blue)[49], water[11], hydrogen peroxide[50], titanyl phthalocyanine[51], sulfuric acid[52], oleic acid[53–55], and the superacid (i.e. with acidity greater than that of 100% pure sulfuric acid[56]) bis-(trfluoromethane)sulfonimide (TFSI)[49, 57–70], in addition to other no chemical treatments[8, 71–75]. The PL enhancement reported to date for 1L-WS₂ treated with different chemical and non-chemical approaches is summarized in Table 1. The effect of chemical passivation of on ηEL combined with gated-PL emission in 1L-TMD-based LEDs was not reported to date, to the best of our knowledge.

Refs.[57–64] reported PL measurements on 1L-TMDs and focused on non-gated samples, thus limiting the modulation of charge density in 1L-TMDs. Ref.[8] performed gated-PL measurements in 1L-WS₂, finding that both TFSI treatment and electrical gating increase ηPL by a factor of up to~10 (at~10^19 cm⁻²s⁻¹ photocarrier generation rate), because both processes reduce the n-type behaviour of 1L-WS₂ and suppress X⁻ formation, thus enhancing X⁰ radiative recombination. However, gated-PL measurements after TFSI passivation were not provided. The activation of trapping states on TFSI-treated 1L-TMDs was not discussed. Ref.[76] carried out EL experiments with TFSI passivation for high-speed

(MHz) modulation, but did not report PL nor EL emission tunability. Therefore, an investigation on how TFSI affects EL emission and modifies gated-PL of 1L-TMD-based devices is required.

Here, we fabricate LEDs with 1L-WS$_2$ as active material on a metal-insulator-semiconductor (MIS) structure. We measure EL and gated-PL before and after TFSI treatment. We find that TFSI increases $\eta_{EL}$ by over one order of magnitude at RT, and PL intensity by a factor~5. Our PL results on TFSI-treated samples agree with previous literature, Table I[57, 59, 60, 69, 70], while EL for TFSI-treated samples is twice than of Ref.[76], reporting both EL and PL characterization before and after TFSI treatment, but not gated-PL. We find that X$^-$ and X$^0$ are present in both EL and PL before TFSI treatment, whereas X$^0$ dominates after. We attribute this to depletion of excess e and changes in the relaxation pathway, induced by the treatment. This paves the way to more efficient 1L-TMDs-based LEDs and excitonic devices.

RESULTS AND DISCUSSION

We use 1L-WS$_2$ as the active light-emitting layer since it has a direct bandgap[77–80], its PL emission is~60 times stronger than 1L-MoS$_2$[39, 78] at RT, $\eta_{EL}$ can be up to~50 times larger than 1L-MoS$_2$[19, 20] at RT, while Refs.[55, 57-68] demonstrated that TFSI treatment increases up to~10-times its PL intensity.

Fig.1a shows the 1L-WS$_2$/hBN/SLG tunnel junction configuration used here, where the metallic electrodes provide contacts to apply a voltage (V) between SLG and 1L-WS$_2$. This is prepared as follows.

WS$_2$ crystals are synthesized using a two-step self-flux technique[81] using 99.9999% purity W and S powders without any transporting agents. Commercial (Alfa Aesar) sources of powders contain a number of defects and impurities (Li, O, Na, and other metals as determined by secondary ion mass spectroscopy). Before growth, W and S powders are thus purified using electrolytic[82] and H$_2$[82] based techniques to reach 99.995% purity. WS$_2$ polycrystalline powders are created by annealing a stoichiometric ratio of powders at 900°C for 3 weeks in a quartz ampoule sealed at 10$^{-7}$ Torr. The resulting powders are re-sealed in a different quartz ampoule under similar pressures and further annealed at 870-910°C with thermodynamic temperature differential (hot to cold zone difference)~40°C. The growth process takes 5 weeks. At the end of the growth, ampoules are cooled to RT slowly (~40°C/hour)[83]. We use this material as bulk source because we previously[83] demonstrated that this has a point defect density~10$^9$-10$^{10}$ cm$^{-2}$, on par or better than previous reports[84].

Bulk WS$_2$, hBN (grown by the temperature-gradient method[85]), and graphite (sourced from HQ Graphene) crystals are then exfoliated by micromechanical cleavage using Nitto-tape[86] on 285nm SiO$_2$/Si. Optical contrast[87] is first used to identify 1L-WS$_2$, SLG, FLG (3-10nm), and hBN(<5nm). The LMs are then charac-
FIG. 1. a) Schematic of LED. Cr/Au electrodes, SLG, FLG, hBN, and 1L-WS₂ are indicated as well as the electrical connection. b) Optical image of device. Scale bar 4µm. The dotted lines highlight the footprint of SLG (black dashed line), FLG (orange dashed line), hBN (blue dashed line), 1L-WS₂ (red dashed line). The green-shaded part corresponds to the active area ~23µm². Cr/Au contacts the bottom SLG; FLG contacts the top 1L-WS₂. Schematic band diagram for (c) V=0V and (d) V>0V for pristine 1L-WS₂ LED and (e) V>0V for TFSI-treated 1L-WS₂ LED. Tuning the SLG E_F (gray dotted line) across the 1L-WS₂ valence band edge, E_v, allows h tunneling from SLG to 1L-WS₂, resulting in current onset and light emission via radiative recombination with e from the n-type 1L-WS₂. The blue circles represent accumulated on 1L-WS₂ due to the MIS structure, while the red circles are h injected into 1L-WS₂ through the hBN barrier. The TFSI promotes a reduction of excess e in the 1L-WS₂.

The LMs are characterized by Raman spectroscopy as discussed in Methods. After Raman characterization of all individual LMs on SiO₂/Si, the FLG/1L-WS₂/hBN/SLG LMH is assembled using dry-transfer as for Refs. [88, 89]. FLG is picked-up from SiO₂/Si using a polycarbonate (PC) membrane on a polydimethylsiloxane (PDMS) stamp (as mechanical support) at 40°C. We use 40°C because this is sufficient to increase the adhesion of the PC film[90], to pick all LMs from SiO₂/Si. Then, FLG is aligned to one edge of 1L-WS₂ on SiO₂/Si and brought into contact using xyz micromanipulators at 40°C, leaving the majority of 1L-WS₂ without FLG cover to be used as active area (AA). AA is the region from where light emission is expected, and it is the overlap area between 1L-WS₂ and SLG (green-shaded part in Fig.1b). Next, FLG/1L-WS₂ is aligned to a hBN flake deposited onto SiO₂/Si and brought into contact using xyz micromanipulators at 40°C. Finally, FLG/1L-WS₂/hBN is aligned to a SLG on SiO₂/Si and brought into contact using xyz micromanipulators at 180°C, whereby PC preferentially adheres to SiO₂[88], allowing PDMS to be peeled away, leaving PC/FLG/1L-WS₂/hBN/SLG on SiO₂/Si. PC is then dissolved in chloroform for ~15mins at RT, leaving FLG/1L-WS₂/hBN/SLG LMH on SiO₂/Si[88, 89]. After LMH assembly, Cr/Au electrodes are fabricated by electron beam lithography (EBPG 5200, Raith GMBH), followed by metallization (1:50nm) and lift-off.

The tunnel junction based on a MIS structure consists of a LMH with 1L-WS₂ as the light emitter. FL-hBN (typically from 2 to 4nm) acting as tunnel barrier, and a SLG electrode to inject holes (h) into 1L-WS₂. We use FL-hBN<5nm so that a low (typically ~5V) driving voltage is sufficient for charge injection to the 1L-WS₂[91, 92]. We employ FLG (~3-10nm) to contact 1L-WS₂, because FLG reduces the contact resistance[93], while Cr/Au electrodes give Ohmic contacts to SLG and FLG[93]. SLG could also be used to contact 1L-WS₂, however, as the optical contrast is higher in FLG than SLG[87, 94], using FLG makes it easier to align it to 1L-WS₂ during transfer. Since TFSI treatment requires direct exposure of 1L-TMDs[57], we place 1L-WS₂ on top of the stack to compare the device performance before and after treatment. We TFSI-treat 4 samples for EL and gated-PL measurements. These are immersed in a TFSI solution (0.2 mg/mL) in a closed vial for 10mins at 100°C[57–59], then removed, dried by a N₂ gun, and annealed on a hot plate at 100°C for 5mins[57–59]. Fig.1b is an image of the 1L-WS₂-LEDs. The FLG electrode is placed on the side of the SLG to avoid direct tunneling of carriers from SLG to FLG, hence keeping as AA the LMH region extended over SLG and 1L-WS₂, green-shaded in Fig.1b. If there is a FLG/SLG overlap, tunneling through FLG-SLG may be possible, not resulting in e-h recombination into 1L-WS₂, hence no EL[6, 25, 38].

Figs.1c,d sketch the band diagram of our LEDs for V=0V and V>0V, respectively. For V=0V (at thermal dynamic equilibrium as indicated in Fig.1c), the Fermi level, E_F, is constant across the junction, and the net current (I) is zero[6, 21, 25, 28, 38]. For V>0V (positive potential on SLG), the SLG E_F is shifted below the 1L-WS₂ valence band energy E_v (Fig.1d), and h from SLG tunnel across the hBN barrier into 1L-WS₂, promoting EL emission by radiative recombination between the injected excess h and intrinsic e[21–24, 28, 35, 38]. The EL emission is expected to increase as a function of tunneling current because of the increasing h injected into 1L-WS₂ available for e-h recombination.

The LMs are characterized by Raman, PL, EL spectroscopy using a Horiba LabRam HR Evolution. The Raman spectra are collected using a 100x objective with numerical aperture (NA)=0.9, and a 514.5nm laser with a power ~5µW to avoid damage or heating. The voltage bias dependent PL and EL are collected using a long working distance 50x objective (NA=0.45). For the PL spectra, we use a λ=532nm (2.33eV) continuous-wave laser in order to excite above the X° emission (~2eV)[9, 10]. The laser power is kept ~80nW to avoid laser-induced thermal effects[2, 9–11]. The spot size A_spot for the PL measurements was calculated by A_spot =
Methods for details of electrical measurements). Voltage (V) and current (I) between source (SLG) and drain (1L-WS₂) electrodes are set (V) and measured (I) by a Keithley 2400 (see Methods for details of electrical measurements).

Fig. 2 plots the Raman spectrum of 1L-WS₂/hBN/SLG on Si/SiO₂ after device fabrication and before current-voltage (I-V) measurements. The Raman modes of each LM can be identified, Table II. For 1L-WS₂, Pos(A₁') and its full width at half maximum, FWHM(A₁') change from ~418.9±0.2cm⁻¹; 3.9±0.2cm⁻¹, before assembly, to ~419.8±0.2cm⁻¹; 3.4±0.2cm⁻¹, after. All the changes in the other modes are close to our spectral resolution and errors, as for Ref.[95]. Pos(A₁') and FWHM(A₁') are sensitive to changes in n-doping[96, 97]. The mechanism responsible for this effect is an enhancement of electron-phonon (e-ph) coupling when e populate the valleys at K and Q simultaneously[97]. The energy of the K and Q valleys is modulated by the A₁ ph[97]. Since the K and Q energies are modulated out-of-phase, charge transfer between the two valleys occurs in presence of the A₁ ph[96, 97]. When the K and Q valleys are populated by e, these are transferred back and forward from one valley to the other[97, 98]. This increases the e-ph coupling of out-of-plane modes, such as A₁[97]. The same process does not occur for p-doping[97]. The reason for this asymmetry between n- and p-doping is due to a much larger energy separation (~230meV[97]) between the VB Γ and K valleys than that (~100meV[97]) of the CB K and Q valleys. From the changes in Pos(A₁') and FWHM(A₁'), and by comparison with Ref.[97], we estimate a reduction in n-doping ~ 5 × 10¹² cm⁻².

For hBN in Fig. 2, Pos(E₂g)~1366.4±0.2cm⁻¹ and FWHM(E₂g)~9.2±0.2cm⁻¹. Although FWHM(E₂g) changes within the error, Pos(E₂g) downshifts ~21cm⁻¹ after assembly, suggesting a contribution from strain (see Methods for comparison between FL- and bulk-hBN Raman). Uniaxial strain lifts the degeneracy of the E₂g mode and results in the splitting in two subpeaks E₂⁺ and E₂⁻ with shift rates ~8.4 and -25.2cm⁻¹/%[99, 100]. For small levels of uniaxial strain (<0.5%) splitting cannot be observed and the shift rate is ~16.8cm⁻¹/%[99, 100]. For biaxial strain, splitting does not occur and E₂g shifts with rate ~39.1cm⁻¹/%[99]. Since we do not observe splitting, the E₂g shift can be attributed to uniaxial or biaxial tensile strain ~0.13% or ~0.06%, respectively.

Fig. 3. a) I as a function of V for 1L-WS₂-LED. Inset: schematic of I-V data collection. Purple, SiO₂(300nm)/Si substrate; black, SLG; blue, hBN; green, 1L-WS₂; yellow, Cr/Au electrodes. The voltage V is applied while the current I is measured. b) EL spectra for different tunneling currents without TFSI treatment. The dashed black line is the PL spectrum for V=0, normalized to the maximum EL intensity...
after LMH assembly, indicating negligible defects[101–103]. In Fig.2 Pos(G)~1585.1±0.2cm⁻¹, FWHM(G)~9.0±0.2cm⁻¹, Pos(2D)~2692.3±0.2cm⁻¹, FWHM(2D)~20.9±0.2cm⁻¹, 1(2D)/I(G)~2.4, and LA(2D)/LA(G)~5.6. These indicate that the SLG is p-doped, with E_F~150±50meV[102–104] by taking into account the average dielectric constant (~3.85) of the environment (ε_SiO₂ ~3.8[105] and ε_hBN ~3.9[106]). E_F~150meV should correspond to Pos(G)~1584.1cm⁻¹ for unstrained SLG[107]. However, Pos(G)~1585.1±0.2cm⁻¹, which implies a contribution from compressive uniaxial (biaxial) strain~0.04% (~0.01%). The strain level for SLG and hBN are different, most likely due to the fact that the SLG is directly exfoliated onto SiO₂/Si, while hBN is picked up and transferred by PDMS stamps, hence, this could induce a larger amount of strain on hBN.

Fig.3a plots the I-V characteristics. For V=0V the current is zero (Fig.1c). When V is applied, an electrical rectification (i.e. diode behavior) with negligible leakage current (I<10⁻¹¹A) for V<0 is seen. A tunneling onset, (i.e. exponential increase of I) is seen at V_ON~4.1V. Fig.3a. V_ON is related to the breakdown electric field (E_bd) across the junction, which depends on the voltage drop on the hBN tunnel barrier and hBN thickness (d) accordingly to E_bd~V_b/d~0.7-1V/nm[91, 92], where V_b is voltage breakdown V_b=qd²/(ε₀ε_hBN), q is the e charge, n is total charge concentration, ε₀=8.854×10⁻¹² F/m and ε_hBN ~3.9[91, 92], so that V_ON can vary between different devices. When V>V_ON, h from SLG tunnel across the hBN barrier into 1L-WS₂, promoting EL emission by radiative recombination between the injected h and majority e in 1L-WS₂ (Fig.1c)[21–24, 35, 38]. The EL intensity~634nm (~1.956eV) increases with tunneling current, as in Fig.3b. The red-shifts (~2nm) in the EL emission in Fig.3b for larger I can be attributed to the E_F shift induced by the MIS structure[6, 31, 33]. FWHM(EL) also increases with I, attributed to the scattering of excitons with extra carriers[6, 109]. This shift and EL broadening is attributed to heating effects at the layered junction[28]. A red-shift~48meV is observed in EL emission~634nm (~1.956eV) with respect to the PL X⁰ emission of the unbiased device (dashed black line, Fig.3b). Fig.3b shows a PL peak position close to X⁻ of unbiased PL (dashed black line, Fig.3b), implying a trionic EL emission, due to excess e in 1L-WS₂[28, 38]. In contrast, no light emission is observed for V<0V and small positive (0<V<V_ON) bias, below the tunneling condition (V_ON~4.1V).

To further understand the EL emission origin, we perform EL and PL spectroscopy at the same V. Fig.4a plots PL spectra at different V. At V=0V, the PL peak is~619.2nm (~2.002eV), assigned to X⁰[9, 78]. By increasing V (i.e. increasing e density in 1L-WS₂), a second peak appears at longer wavelengths (~630nm,~1.968eV), due to X⁻~9–11, 108). The dashed lines in Fig.4a describe the peak position evolution of X⁰ and X⁻ emission for different V. For V>0V, the X⁻ intensity gradually decreases and nearly vanishes, while X⁻ shifts to longer wavelengths, as in Fig.3b. The similar tunneling current, EL agrees in energy and shape in EL and PL, Fig.4b. This is confirmed by Fig.4c, where EL and PL peak positions are plotted for 4 devices, showing EL and PL emission at similar wavelengths. Thus, EL predominantly originates from X⁻[6, 9, 10, 21, 38]. The variations in X⁻ for different
FIG. 4. a) Evolution of PL as a function of $V$. For comparison, an EL spectrum for $I\sim 10^{-11}$A is shown (red). The dashed lines are guides to the eye for the $X^0$ and $X^-$ positions. In all PL measurements up to 3V, $I<10^{-11}$A. At 4V, $I\sim 10$nA, indicating tunneling through hBN into 1L-WS$_2$. b) Normalized gated-PL and EL spectra of a representative 1L-WS$_2$ LED near the threshold bias highlighting similarity of the emission spectra. c) EL and PL positions from 4 different devices. The dashed line plots the unbiased PL position of $X^0$ measured in Fig.3b. The emission values in (c) are derived by fitting with Lorentzians the PL and EL spectra at similar $I$ level, considering the centre of the main emission peak (higher spectral weight). The error bars are within the size of the symbols.

FIG. 5. 514.5nm Raman spectra of pristine (black line) and TFSI-treated (red line) 1L-WS$_2$/hBN/SLG. The SLG and hBN Raman modes are labelled, as well as the modes for 1L-WS$_2$, as for Table II. The 150-450cm$^{-1}$ (1300-2800cm$^{-1}$) ranges are normalized to the Si (2D) peaks, respectively. The $E_{2G}$ peak is multiplied by 10 for better visualization.

FIG. 6. Fitting of PL spectra for (a) pristine and (b) TFSI-treated 1L-WS$_2$ on SiO$_2$/Si, for 532nm excitation. LEDs are due to changes in charge carriers density across different samples. The charge density variation can be due to the number of vacancies in 1L-WS$_2$[41] and external impurities (PC residues and adsorbed water) after LED fabrication, which may vary from sample to sample.

We now consider the origin and consequences of excess $e$ in 1L-WS$_2$ for EL emission induced by $V$. Besides the intrinsic charge carriers in 1L-WS$_2$ (typically $n$-type due to S vacancies[41]), there is also an electrostatically induced charge in 1L-WS$_2$ when $V>0V$. A SLG/hBN/1L-WS$_2$ tunneling junction acts as a MIS capacitor[6, 28, 38]. When $V>0$ is applied to SLG, inducing positive charges
in SLG, there is an opposite (negative) charge induced
in 1L-WS₂[6, 28, 38], thus making the charge density on
1L-WS₂ larger than for \( V=0 \). When \( V>V_{ON} \), \( h \) will be
jected by tunneling into 1L-WS₂ (Fig.1d), hence, \( h \) will
recombine with \( e \). Consequently, the EL emission originates
from \( X^- \) states. However, the radiative recombination efficiency (defined as the number of \( e-h \) pairs that
recombine by emission of a photon divided by total num-
ber of \( e-h \) pairs) of \( X^- \) is lower than \( X^0 \) because of the small (∼30meV) binding energy of trions[42]. Thus, to
gain higher \( \eta_{EL} \), one should favor \( X^0 \) EL emission by low-
ering the unbalanced free-carriers concentration in 1L-
TMDs by either gate modulation[6, 12, 28, 31, 36, 38],
physical[112, 113], or chemical doping[11, 25].

We thus treat 1L-WS₂ using TFSI to reduce doping
and favor \( X^0 \) emission under bias and investigate
the effects on EL emission and gated-PL. Fig.5 plots
representative Raman spectra before (black) and after
(red) TFSI treatment. By comparing the spectra before
and after TFSI treatment, and the fits for 1L-WS₂
in Table II, we do not observe significant changes
in peak position and FWHM. However, there is an
overall intensity increase of the Raman peaks of~50%,
compared to the Si peak. This indicates a reduction of
\( n \)-doping induced by TFSI treatment, because S
vacancies in 1L-TMDs are commonly associated to
\( n \)-type behaviour and the reduction of these defects will
reflect in \( p \)-type doping fingerprint[57–59, 69]. \( \text{Pos}(A') \)
is unaffected by TFSI treatment, which suggests that
the reduction in the intrinsic 1L-WS₂ \( n \)-doping
induced by TFSI is \(<10^{12}\text{cm}^{-2}[97] \). Although TFSI
is able to \( p \)-dope SLG when it is in contact with the
TFSI solution[114], Fig.5 shows negligible (within the
errors[95]) changes in the SLG (e.g. before (after):
\( \text{Pos}(G)\sim1585.1 \) \((1585.0)\pm0.2\text{cm}^{-1}, \text{FWHM}(G)\sim9.0\)
\((9.1)\pm0.2\text{cm}^{-1}). \( \text{Pos}(2D)\sim2692.3 \)
\((2692.2)\pm0.2\text{cm}^{-1}, \text{FWHM}(2D)\sim20.9 \)
\((20.8)\pm0.2\text{cm}^{-1}, \text{I}(2D)/\text{I}(G)\sim2.4\)
\((2.4), \text{and } \text{A}(2D)/\text{A}(G)\sim5.6 \) \((5.6)\) and hBN (e.g.
before (after): \( \text{Pos}(E_{2g})\sim1366.4 \) \((1366.5)\pm0.2\text{cm}^{-1}
and FWHM(E_{2g})\sim9.2 \) \((9.1)\pm0.2\text{cm}^{-1}) \) Raman spectra after
TFSI treatment, as both are protected by the top 1L-W₂.

Fig.6a plots a representative PL spectrum of 1L-
WS₂ embedded in the LMH before TFSI treatment,
and Fig.6b after. For the pristine case, there are two
components, fitted by two Lorentzians~618.7nm with
FWHM~8.4nm and~629.1nm with FWHM~18.1nm,
which correspond to \( X^0 \)[78, 80] and \( X^- \) emission,
respectively[108, 110]. The observation of the \( X^- \) emis-
ion and a broader FWHM(X⁻→FWHM(X₀)) is related
to the \( n \)-type doping behavior of the 1L-WS₂[115], which
favors the \( X^- \) recombination. For non-biased devices,
the spectral weight (defined as the area of each peak)
of the PL emission indicates a majority emission due
to \( X^0 \). After treatment, the PL emission evolves to a
main single peak~618.1nm with FWHM~8.7nm, accom-
pnied by a~4-fold increase in PL intensity. The PL

![FIG. 7. I-V curves of 3 LEDs before (solid black lines) and after (dashed red lines) TFSI treatment.](image)

intensity enhancement induced by the TFSI is consistent
with that reported in Refs. [8, 49, 55, 57, 59, 60, 69, 70]
The changes in spectral weight of \( X^0 \) and \( X^- \) emission
and the FWHM after treatment can be assigned to a re-
duction in the \( e \)-density in 1L-WS₂[57–59], in agreement
with our Raman analysis. Refs.[53–55, 57–68] reported
that PL enhancement depends on sample quality (de-
fects) and may vary 1 to 10 times. We observe a PL
increase~5±1-times, as for Refs.[53–55, 57–68].

Fig.7a plots typical \( I-V \) characteristics of 3 devices before
(solid black lines) and after (dashed red lines) TFSI
treatment. \( I_{ON} \) is not affected by the treatment. \( V_{ON} \)
is related to the breakdown electric field \( E_{bd} \) across the
junction, which depends on the voltage drop on the hBN
tunnel barrier and hBN thickness[91, 92]. Our LED-
devices use 2 to 4nm hBN as tunnel barrier. Conse-
quently, \( V_{ON} \) can vary between different devices. Our
results on the same device demonstrate that TFSI treatment
does not induce changes in the tunneling because the
chemical treatment does not modify the MIS struc-
ture. Figs.9a,b show EL collected before and after TFSI,
respectively, for different \( I \). In both cases, EL is triggered
for similar current levels (\( I<5\mu A \)) and the intensity
increases linearly with \( I \), Fig.9c. The EL intensity slope
as a function of current density (\( I \) divided by \( AA \)) is
affected by TFSI. For pristine-LEDs we get an average
slope \( \sim1.4±0.3 \), while after TFSI \( \sim13.5±1.1 \), with 1
order of magnitude \( \eta_{EL} \) increase, Fig.9c. The red-shifts
in the EL emission with \( I \) increase in pristine (,<6nm) and
TFSI treated LEDs (<5nm), Figs.9a,b, can be assigned to \( E_F \)
shift induced by the MIS structure[6, 31, 33], or heating
effects at the layered junction[28].

Next, we estimate the external quantum efficiency
(EQE) of our LEDs. This is defined as the ratio between the number of emitted photons \((N_{ph})\) and that of injected \(h\) per second \((N_h)\)[116]:

\[
\text{EQE} = \frac{N_{ph}}{N_h} = \frac{\sum \lambda N_{ph-counts}}{N_h \times \eta_{sys}}, \quad (1)
\]

where \(\sum \lambda N_{ph-counts}\) is the sum of the total photons collected by the spectrometer over the measured spectral range, \(A_{sys} = A/A_{pot}\), where \(A_{pot}\) is the microscope objective spot size \(A_{pot} \approx 2.2\mu m^2\), with \(\lambda = 618nm\) and \(\eta_{sys} = 0.45\), and \(N_h = 1 \times t/q\), where \(t\) is the acquisition time, and \(q\) the e charge. The efficiency factor (defined as the ratio between the photons collected by the detector and the emitted photons by EL at the sample position) of our setup, including all optical components and spectrometer, is \(\eta_{sys} = 0.0051\), see Methods.

From Eq.1 we get \(\text{EQE} \approx 0.025\% \pm 0.01\%\) and \(\sim 1.95\% \pm 0.32\%\) for pristine- and TFSI-treated LEDs, respectively, corresponding to a \(\sim 8.7 \pm 1.5\)-fold increase, thus demonstrating that TFSI can boost EQE by almost one order of magnitude. \(\text{EQE} \approx 0.2\%\) is better than previously reported for 1L-WS\(_2\)-based EL (\(\sim 0.1\%)\) on a SiO\(_2\)/SiN microcavity[35], bulk organic (2,7-bis[9,9-di(4-methylphenyl)-fluoren-2-yl]-9,9-di(4-methylphenyl)fluorene) emissive layer (\(\sim 0.1\%)\)[117], and semiconducting (6,5) single-wall nanotubes (\(\sim 0.1\%)\)[118]. The WS\(_2\)-LED performance can be further improved if placed within a photonic cavity[25, 119–127].

To evaluate the cavity enhanced EQE, we extract the performance metrics from our reference measurements on SiO\(_2\)/Si and project them on simulation results for a cavity system. We first estimate the reference internal quantum efficiency \(\text{IQE}_{\text{ref}} = \text{EQE}_{\text{ref}}/\eta_{\text{extr,ref}}[116]\), where \(\eta_{\text{extr,ref}}\) is the extraction efficiency on SiO\(_2\)/Si, defined as the number of photons emitted into free space over the total number of emitted photons[116]. Emitted photons not reaching free space include those absorbed and/or lost into the reference substrate. By 3d finite-difference time-domain method (FDTD) simulations[128, 129], of a 10\(\times\)10\(\mu m^2\) reference system with a single transverse electric (TE) (i.e. parallel to the surface) point dipole emitter on the surface at \(\lambda = 624nm\), we calculate \(\eta_{\text{extr,ref}} \sim 14\%\), i.e., a significant (\(\sim 86\%)\) portion of the emitted light is absorbed and lost into the substrate. This yields for the TFSI-treated LED \(\text{IQE}_{\text{ref}} \sim 1.43\%\). In turn, \(\text{IQE}_{\text{ref}}\) is related to the ratio of radiative to total recombination rates, i.e. \(\text{IQE}_{\text{ref}} = \Gamma_{R,ref}/(\Gamma_{R,ref} + \Gamma_{NR})[116, 130]\), where \(\Gamma_{R,ref}\) and \(\Gamma_{NR}\) denote the radiative and non-radiative rates, respectively. For simplicity we assume \(\Gamma_{NR} \approx \Gamma_{NR,eff}\) independent of substrate, i.e., the non-radiative relaxation pathways are unaffected by the environment. Thus \(\Gamma_{NR} = \Gamma_{NR,eff}(\text{IQE}_{\text{ref}})^{-1} - 1\). Inside a cavity, the radiative density of states increases, leading to a proportional increase in radiative rate due to the Purcell effect[130, 131]. Thus, \(\text{IQE}_{\text{cav}} = \Gamma_{R,cav}/(\Gamma_{R,cav} + \Gamma_{NR})\), where \(\Gamma_{R,cav} = \eta_{p}\Gamma_{R,ref}\) and \(\eta_{p}\) is the relative Purcell enhancement factor calculated by FDTD as the ratio of total light (free and lost) emitted by a point dipole in the cavity over the total light emitted on the reference substrate. Combining the above relations, we get \(\text{IQE}_{\text{cav}} = 1 + \eta_{p}(\text{IQE}_{\text{SiO}2}/\text{Si} - 1)\). The external quantum efficiency becomes \(\text{EQE}_{\text{cav}} = \eta_{\text{extr,cav}}\text{EQE}_{\text{cav}}\), with \(\eta_{\text{extr,cav}}\) the extraction efficiency of the cavity evaluated by FDTD. The photonic cavity, shown in the top inset of Fig.8, is asymmetric to enable maximal unidirectional emission. NbO\(_2\)/SiO\(_2\) bilayers are used for the Bragg mirrors, with \(N_p\) NbO\(_2\)/SiO\(_2\) periods on top, a SiO\(_2\) cavity in the middle, and an Ag back mirror. At \(\lambda = 624nm\) the reflective indices are \(n_{\text{NB}} = 2.325[132], n_{\text{SiO}2} = 1.457[133], n_{\text{Ag}} = 0.0581 + i4.212[134], n_{\text{SLG}} = 2.787 + i4.43[135, 136], n_{\text{SiBN}} = 2.12[137], n_{\text{WS}2} = 5.38 + 0.382[138]\). The layer thicknesses are \(d_{\text{NB}x}\)=67nm, \(d_{\text{SiO}2}\)=107nm and \(d_{\text{WS}2}\)=191nm, while 1L-WS\(_2\)/hBN(3nm)/SLG is placed in the middle of the SiO\(_2\) cavity layer. FDTD simulations predict the cavity enhanced EQE as a function \(N_p\) as for Fig.8. For \(N_p=1\) the EQE gets a \(\times 5.75\) enhancement, reaching \(\sim 1.15\)%, attributed to a Purcell enhancement of \(\times 1.15\) and a \(\times 5\) increase in extraction efficiency. Cavity effects also enhance the directionality of light, as shown in the bottom inset of Fig.8 for the SiO\(_2\)/Si reference structure as well as for the \(N_p=1\) and \(N_p=2\) cavity structures. To quantify the enhancement in the vertical direction (e.g. were we to use a narrow numerical aperture, \(NA = 0.0125[127]\)), we also plot the normal emission measurements through a 1d calculation in Fig.8. These are consistent with the angular plots of full 3d systems (lower inset of Fig.8) and predict an optimal cavity with \(N_p=3\) and relative normal emissivity enhancement of \(\times 16\). Further enhancement mechanisms can also be considered, such as plasmonic cavities and/or antenna-coupling[139–145], as well as dielectric domes on top of the device to further boost extraction.

We now consider the EL emission features induced by TFSI treatment. By comparing EL before and after TFSI (Figs.9a,b), a blue-shift in EL is observed. In pristine-LEDs, the main EL emission is can be fitted with a single Lorentzian at \(\sim 641.8\)nm with FWHM\(\sim 28.6\)nm, Fig.10a, whereas after treatment it can be fitted with two-Lorentzian at \(\sim 625.9\)nm with FWHM\(\sim 28.6\)nm and \(\sim 640.1\)nm. The observation of \(X^0\) emission and similar FWHM\((X^-)\) and Pos\((X^-)\) after TFSI treatment suggests that there is a reduction in n-doping behavior, consistent with PL and Raman analysis. The fact that we observe \(X^-\) emission in EL after TFSI treatment indicates that 1L-WS\(_2\) is still n-doped, which can be caused by \(e^-\) injection from the \(V^0\) bias in the MIS structure[6, 28, 33, 109]. Fig.10c plots the EL peak position before and after treatment in 4 devices. After treatment, the EL emission shifts to shorter wavelengths, where \(X^0\) is expected[77, 78] (dashed line in
Fig. 8. TFSI-treated 1L-WS$_2$-LED enhanced EQE (3d calculation) in a cavity as a function of Bragg $N_P$ periods (see top inset). Also plotted is the emissivity enhancement for vertical emission (1d calculation). The angular far-field intensity distribution for 3 device cases (3d calculations) is shown in the lower inset. All calculations are performed assuming $\lambda(EL) = 624$nm.

Fig. 9. EL spectra from (a) pristine and (b) TFSI-treated 1L-WS$_2$-LEDs for different tunneling currents. AA$\sim$21$\mu$m$^2$. c) EL intensity as a function of tunneling current divided by AA for pristine (black) and TFSI-treated (red) 1L-WS$_2$-LEDs (3 devices). The dashed lines are a linear fit to the data. The emission values presented in (c) were taken by fitting with Lorentzians the EL spectra for every $I$, and the maximum intensity of the main EL peak was considered. The error bars for this fitting are within the size of the symbols presented.
FIG. 10. EL spectra of (a) pristine and (b) TFSI-treated LEDs at similar tunneling current ~12nA, fitted with Lorentzians. (c) Position of EL emission for different LEDs before (black) and after (red) TFSI. The values in (c) are fits with Lorentzians of EL spectra at similar I, considering the centre of the main emission peak (higher spectral weight). The error bars are within the size of the symbols. Color-plot of the gated PL of (d) pristine and (e) TFSI-treated LED at similar laser excitation power and integration time.

CONCLUSIONS

We demonstrated a one order of magnitude enhancement in EL emission of 1L-WS2-LEDs by performing TFSI treatment. EL predominantly originates from tri- ons in pristine devices, while neutral excitons dominate in treated ones. The neutral excitonic emission is also restored in 1L-WS2 gated-PL measurements. We attribute these changes to a reduction of n-doping of 1L-WS2, as well as changes in the relaxation and recombination pathways within 1L-WS2. This paves the way to more efficient 1L-TMDs-based LEDs, and sheds light into tunability of the excitonic emission of these devices.

METHODS

Raman characterization of LMH individual constituents

Raman spectroscopy allows us to monitor LMs at every step of device fabrication. This should always be performed on individual LMs before and after assembly in LMHs and devices. This is an essential step to ensure reproducibility of the results, but, unfortunately, this is often neglected in literature.

Ultralow-frequency (ULF) Raman spectra in the range ~10-50 cm<sup>-1</sup> probe shear (C), corresponding to layer motion parallel to the planes, and layer breathing modes (LBM), corresponding to the motion perpen-
spectra of 1L-WS\(_2\) (red) and bulk-WS\(_2\) (black) on Si/SiO\(_2\), normalized to the Si peak, with labels as for Table II
dicular to them\([102, 146–148]\). Pos(C)\(_N\) can determine the number of layers\([146–149]\) \(N=\pi(2 \cos^{-1}\frac{\text{Pos(C)\(_N\)}}{\text{Pos(C)\(_\infty\)}})^{-1}\), with Pos(C)\(_\infty\) the bulk Pos(C).

Fig.11 plots the Raman spectra of non-treated 1L-WS\(_2\) and bulk-WS\(_2\). In Fig.11a, the C mode and LBM are not observed for 1L-WS\(_2\), as expected\([146–148]\).

In bulk-WS\(_2\), Pos(C)\(\sim 26.9 \pm 0.14\text{cm}^{-1}\). The spectral resolution\(\pm 0.14\text{cm}^{-1}\) for the ULF region is obtained as for Ref.\([95]\). We observe two additional peaks\(\sim 28.7 \pm 0.14\text{cm}^{-1}\) and \(46.4 \pm 0.14\text{cm}^{-1}\), respectively, in agreement with Refs.\([150–152]\). These do not depend on \(N\)[150, 151] and are seen because 514.5nm \((2.38\text{eV})[154, 155]\). This gives rise to a resonant process\([153–157]\), which occurs because the laser energy matches the electronic transition of the B exciton, revealing features associated with intervalley scattering mediated by acoustic phonon\([158–160]\). A similar process also happens in 1L-MoS\(_2\)[150, 151] and other 1L-TMDs\([158–160]\).

Although our ULF filters cut in 1L-WS\(_2\) [153–157], and \(\sim 20\text{meV}\) above the bulk-WS\(_2\) B exciton \((\sim 2.38\text{eV})[154, 155]\). This gives rise to a resonant process\([153–157]\), which occurs because the laser energy matches the electronic transition of the B exciton, revealing features associated with intervalley scattering mediated by acoustic phonon\([158–160]\). A similar process also happens in 1L-MoS\(_2\)[150, 151] and other 1L-TMDs\([158–160]\).

Although our ULF filters cut \(6\text{cm}^{-1}\), the LBM is not detected in bulk-WS\(_2\), as its frequency is expected to be \(<10\text{cm}^{-1}\)[148], because this resonant process with a 514.5nm laser reduces the signal-to-noise ratio in this spectral region\([150]\).

The high-frequency (HF) Raman spectra of non-treated 1L-WS\(_2\) and bulk-WS\(_2\) (Fig.11b) show various peaks, Table II. The first order Raman modes, i.e. \(E^'\), \(A_1^\prime\) in 1L-WS\(_2\)[77–80] and \(E_2^\prime\), \(A_2^\prime\) in bulk-WS\(_2\)[77–80]. \(E^\prime\) \((E_{12g})\) and \(A_1^\prime\) \((A_{1g})\) correspond to in-plane and out-of-plane optical phonon for 1L(bulk)-WS\(_2\). Their nomenclature for 1L and bulk differs due to the different crystal symmetry\([77–80]\). In 1L-WS\(_2\) we get Pos\((E^\prime)\)\(\sim 356.8 \pm 0.2\text{cm}^{-1}\), FWHM\((E^\prime)\)\(\sim 3.2 \pm 0.2\text{cm}^{-1}\), Pos\((A_1^\prime)\)\(\sim 418.5 \pm 0.2\text{cm}^{-1}\), FWHM\((A_1^\prime)\)\(\sim 1.3 \pm 0.2\text{cm}^{-1}\). In bulk-WS\(_2\) we have Pos\((E_{12g})\)\(\sim 356.8 \pm 0.2\text{cm}^{-1}\), FWHM\((E_{12g})\)\(\sim 1.5 \pm 0.2\text{cm}^{-1}\), Pos\((A_{1g})\)\(\sim 420.8 \pm 0.2\text{cm}^{-1}\), FWHM\((A_{1g})\)\(\sim 2.1 \pm 0.2\text{cm}^{-1}\).

In 1L-WS\(_2\) the difference in peaks’ position \([\text{Pos}(E^\prime)\text{-Pos}(A_1^\prime)]\) is \(\sim 61.7\text{cm}^{-1}\) while this is \(\sim 64.0\text{cm}^{-1}\) in bulk-WS\(_2\), further corroborating the identification of 1L[77]. In the HF spectra of 1L- and bulk-WS\(_2\) we also observe the 2LA(M) mode, involving two longitudinal acoustic (LA) ph close to the M point[77–79]. For 1L-WS\(_2\) Pos\((2LA(M))\sim 351.9 \pm 0.2\text{cm}^{-1}\) and FWHM\((2LA(M))\sim 9.2 \pm 0.2\text{cm}^{-1}\), whereas for bulk-WS\(_2\) Pos\((2LA(M))\sim 350.6 \pm 0.2\text{cm}^{-1}\) and FWHM\((2LA(M))\sim 8.3 \pm 0.2\text{cm}^{-1}\). The 2LA(M) mode originates from a second-order double resonant process\([158–160]\), where momentum conservation is satisfied by two LA ph with opposite momenta around K- and M-points\([159]\), therefore sensitive to differences in band structure between bulk and 1L-WS\(_2\)[77, 161].

\[\frac{I(A_{1g})}{I(E_{1g})}\sim 3.2\text{ in bulk-WS}_2\text{, with I is the peak height, is higher than }\frac{I(A_1^\prime)}{I(E^\prime)\sim 0.8\text{ in 1L-WS}_2\text{. I}(2LA)/I(E_{1g})\sim 1\text{ in bulk-WS}_2\text{, and lower than }I(2LA(M))/I(E^\prime)\sim 1.7\text{ in 1L-WS}_2\text{. This can be explained considering that the main first-order (E, A_1^\prime) and second-order (2LA(M)) Raman modes are enhanced for 2.41eV excitation, due to exciton-ph coupling effects involving }\]}
The latter has 2 Raman-active modes[164, 165], flake (black curves) and bulk-hBN (red curves). from the LO and TO branches at Γ[77–80]. E ∼ 2 cm⁻¹ with FWHM(E ∼ 2 cm⁻¹) in bulk-hBN is due to a change in band structure from direct bandgap to indirect in bulk-hBN[77–80], which changes the double resonance conditions[158–160].

The Raman spectrum of 1L-WS₂ also shows 8 peaks in the range 170-350 cm⁻¹ (Fig.10b and Table II). LA(M) and LA(K) correspond to one-ph processes originating from the LA branch at the M- and the K-points, respectively[77–80]. Since LA(M) and LA(K) and E₂g(M) are one-ph processes from the edge of the BZ (q=0)[77–80], they should not be seen in the Raman spectra considering that, due to the Raman fundamental selection rule[163], one-ph processes are Raman active only for ph with q~0, whereas for multi-ph scattering the sum of ph momenta needs to be ~0[158–161]. However these modes can be activated in presence of defects, as these can exchange momentum with ph, such that the sum of the momenta in the process is ~0[77–80]. A₁g(K)-LA(K), A₁g(M)-LA(M), A₁g(M)-ZA(M), LA(M)+TA(M) in bulk-WS₂ and A₁g(K)-LA(K), A₁g(M)-LA(M), A₁g(M)-ZA(M), LA(M)+TA(M) in 1L-WS₂ are combinational modes, and Raman allowed[77–80]. E₂g(M) correspond to a one-ph process originating from the transverse optical (TO) branch at the M-point[77–80]. E₂g(T) is a degenerate mode originating from the LO and TO branches at Γ[77–80].

Fig.12 plots the Raman spectra of a ~3nm hBN flake (black curves) and bulk-hBN (red curves). The latter has 2 Raman-active modes[164, 165], C and E₂g. In Fig.12a Pos(C) = 1585.0 ± 0.2 cm⁻¹ with FWHM(1584.3cm⁻¹) ~ 1.2 cm⁻¹ for bulk-hBN and Pos(C) = 1584.3 ± 0.2 cm⁻¹ for the hBN flake. In bulk-hBN Pos(C) = 1584.3 ± 0.2 cm⁻¹, with μ = 6.9 × 10⁻² kg A⁻² the mass of one layer per unit area, c the speed of light in cm s⁻¹, and α the spring constant associated to the coupling between the adjacent layers[95, 148]. From this, we get α = 16.9 × 10⁻¹⁸ Nm⁻³. From ∼ N=π(2 cos⁻¹(p_{c}(C) \/ p_{c}(C)))⁻¹, we get N = 6 ± 1 for the 3nm thick flake (measured with a Dimension Icon Bruker AFM in tapping mode) as shown in the inset of Fig.12b. In Fig.12b Pos(E₂g) = 2725 ± 0.2 cm⁻¹ and FWHM(E₂g) ~ 10.1 ± 0.2 cm⁻¹ for FL-hBN, and Pos(E₂g) = 2725 ± 0.2 cm⁻¹ with FWHM(E₂g) ~ 7.6 ± 0.2 cm⁻¹ for bulk-hBN. The peak broadening ~1.5 cm⁻¹ in FL-hBN can be attributed to strain variations within the laser spot, as thinner flakes conform more closely to the roughness of the underlying SiO₂[95]. This is consistent with the fact that thicker hBN have lower root mean square (RMS) roughness[88, 92, 95, 166], e.g. 300nm SiO₂ has RMS roughness ~1 nm[92], 2-8nm hBN has RMS roughness ~0.2-0.6 nm[95], while >10nm hBN thick presents RMS roughness ~0.1 nm[88, 92].

The red curves in Figs.13a,b are the Raman spectra of SLG on SiO₂/Si before LMH assembly. Pos(G) = 1584.9 ± 0.2 cm⁻¹ with FWHM(G) = 7.7 ± 0.2 cm⁻¹, Pos(2D) = 2685 ± 0.2 cm⁻¹ with FWHM(2D) = 26.3 ± 0.2 cm⁻¹, I(2D)/I(G) = 0.85, A(2D)/A(G) = 3.3. These indicate a p-doping[102–104] with E_F ~ 200 ± 50 meV. No D peak is observed, thus negligible defects[101–103]. Pos(G) and Pos(2D) are affected by the presence strain[102, 103]. Biaxial strain can be differentiated from uniaxial from the absence of G-peak splitting with increasing ϵ[167, 168], however at low (<0.5%) ϵ the splitting cannot be resolved[167, 168]. Thus, the presence (or coexistence) of biaxial strain cannot be ruled out. For uniaxial (biaxial) strain, Pos(G) shifts by ∆Pos(G)/∆ϵ ≈ 23(60) cm⁻¹/%[167, 168]. Pos(G) also depends on doping[104, 107]. E_F ~ 200 ± 50 meV should correspond to Pos(G) ~ 2584.3 cm⁻¹ for unstrained SLG[107]. However, in our experiment Pos(G) ~ 2586.9 ± 0.2 cm⁻¹, which implies a contribution from compressive uniaxial (biaxial) strain ~0.1% (~0.04%). The black curves in Figs.12a,b show the Raman spectrum of the FLG electrode on SiO₂/Si. Pos(G) = 1581.2 ± 0.2 cm⁻¹ with FWHM ~ 12.0 ± 0.2 cm⁻¹, Pos(2D₁) ~ 2694.0 ± 0.2 cm⁻¹ with FWHM ~ 48.0 ± 0.2 cm⁻¹, and Pos(2D₂) ~ 2725.0 ± 0.2 cm⁻¹ with FWHM ~ 32.0 ± 0.2 cm⁻¹. Pos(C) ~ 41.4 ± 0.14 cm⁻¹, corresponding to N = 5.

**Electrical characterization**

Electrical characterization is performed at RT and in air, using two micrometric (xyz) positioners (Lambda EverBeing EB-050) with 10 μm W tips to provide signal and check the read-out. A Keithley 2400 sourcemeter is used as a DC source for the voltage potential V, with constant reading of the current I. The I-V curves are measured in a two-probe station, with one the probes touching the Cr/Au pad connecting the SLG, while the second connecting to the pad associated to 1L-WS₂. The 1L-WS₂ electrode is grounded to keep the electric field aligned from SLG towards 1L-WS₂, inducing ε carries on 1L-WS₂ for V>0. For the I-V curves, the voltage sweep is 10 mV/s and the data acquisition is interrupted as soon as I has exponential rise, to avoiding damage. The first measurement is the I-V curve, followed by EL, then, gated-PL spectra collection. For EL and gated-PL, the voltage is set manually to the desired V, then either EL or PL are acquired for 10 and 1s, respectively. A new V is then set by hand, followed by the next data acquisition. As soon as I reaches the values measured in the
Spectrometer efficiency

The $\eta_{sys}$ of our spectrometer is derived as follows. We use a 50x objective (NA=0.56). Hence, the solid angle is $\theta=(1-\cos \theta) \times 2\pi r$, where $\theta=\arcsin(NA/n)$, and $n$ is the refractive index. Assuming $n=1$ we get $\theta=0.672$. Thus, $M_{50x-corr}=\theta/(4\pi) \approx 100\% - 5.4\%$.

In our Horiba system, the optical path from $M_{50x}$ to CCD includes 7 Mirrors ($M_{eff} \approx 83\%$), a slit ($S_{eff} \approx 90\%$), a grating ($G_{eff} \approx 60\%$) and a CCD detector ($CCD_{eff} \approx 85\%$). Therefore, the calculated overall collection + Horiba efficiency is: $M_{50x-corr} \times M_{eff} \times S_{eff} \times G_{eff} \times CCD_{eff} \approx 0.0067$. To experimentally validate the calculation, we use a 0.5pW laser at 632.8nm and measure the counts at the CCD detector $N_{counts}=149748$. The photon energy at 632.8nm is $E_{ph}=(1.24/0.638) \times 1.6e^{-9}=3.13e^{-9}$ J. The laser power is $P_{opt}=0.5e^{-12}$ J/s. As a result, if the system efficiency is 100%, we expect to get $0.5e^{-12}/3.13e^{-9}=1597444$ counts. Therefore, the Horiba system efficiency is $Syst_{eff}=149748/1597444=0.094$. Considering $M_{50x-corr}$ we get an overall collection + Horiba efficiency $M_{50x-corr} \times Syst_{eff}=0.054 \times 0.094=0.0051$, consistent with the theoretical estimation.
